Improvement of the E-Field antenna for susceptibility testing

Abstract. The paper deals with shape optimization of the E-Field generating antenna for susceptibility testing according to military EMC standard. An optimized antenna shape allows to minimize the cost of power amplifier used for testing and thus brings substantial economical benefits. The optimal design uses numerical FEM model of antenna and applies Levenberg-Marquardt algorithm to minimize the objective function correlated with non-symmetrical pattern of generated field.

The problem

Susceptibility testing according to the military standards includes exposure to E-Field of large intensity and broad frequency range [1]. According to the last and penultimate issues of this standard (F edition: 2007), and (E edition: 1997), exposure frequency range extends from 2MHz to 40GHz, while the range of field strengths range from 10 V/m, by 20 V/m and 50 V/m up to 200 V/m depending on the application in different types of troops. According to an even earlier release of this standard (D edition: 1993), exposure frequency range starts from 10 kHz. There is still market demand for research in the field of 10 kHz.

In this tests, the generating antenna is located 110 cm from the tested object (EUT = Equipment Under Test) placed on a long table (equipment table) with conductive top level (Fig.1.). The minimal size of the shielded room can be estimated as $7 \times 5 \times 3$ meters.

The mathematical model

The electric and magnetic fields described by Maxwell equations can be in the case of time-harmonic fields reduced to the vector Helmholtz wave equation [5]. In our problem the domain of interest ($\Omega$) is surrounded by perfect electrical conductors—we shall reference such boundary by $\Gamma_e$. The $\Omega$ is electrically homogeneous. The wave equation in terms of the electric field, $E$ can be written as

$$\nabla \times \nabla \times E - k_0^2 \varepsilon_r \mu_r E = 0$$

in $\Omega$,

with the boundary condition

$$n \times E = 0$$

on $\Gamma_e$.

$\varepsilon_r$ and $\mu_r$ represent respectively the relative permittivity and permeability (both equal 1 in our case) and $k_0$ is the operating wavenumber

$$k_0 = \frac{2\pi f_0}{c},$$

where $f_0$ is the operating frequency and $c$ is the speed of light in free space [6].

For our purpose implementation of the above boundary problem (1),(2) is not sufficient, yet it does not obey the antenna. We might simulate it using the common procedure described i.e. in [6]. However, to improve the radiation pattern in the shielded room it is not necessary to make the full 3D vector field simulation. The preliminary experiments (which will
be briefly mentioned later) showed us, that the low frequency range is crucial: if an antenna produces better field for low frequencies, it will operate better in the higher frequencies as well. The "low frequency" means $f_o$, for which the wavelength is much smaller than the antenna size: for EFG-3B it is equivalent to $f_o < 30$ MHz.

To predict the field pattern for the low frequencies it is sufficient to solve the scalar Helmholtz equation for the electric scalar potential

$$\nabla^2 V - k_o^2 \varepsilon_r \mu_r V = 0, \tag{4}$$

with the natural boundary condition on the conducting, grounded walls (ant the equipment table)

$$V = 0 \quad \text{on} \quad \Gamma_c, \tag{5}$$

and the antenna simulated in form of the boundary conditions

$$V = \pm U \quad \text{on} \quad \Gamma_a, \tag{6}$$

where $\Gamma_a$ represents the antenna surface.

The numerical model

Numerous numerical methods can be used to solve the (4)-(6) boundary problem. The authors’ experience with finite element method was the key factor of the choice.

Using the weighted residual, Galerkin approach allows us to transform the boundary problem (4)-(6) into the following weak form

$$\int_{\Omega} (\nabla V \cdot \nabla u - k_o^2 \varepsilon_r \mu_r V \cdot u) \, d\Omega = 0, \tag{7}$$

where $u$ is the so-called test function \[7\]. The boundary conditions (5)-(6) are, strictly speaking, enforced to the system of algebraic equations obtained from (7).

Equation (7) can be directly coded into Python or C++ program with help of the Dolfin and FFC components of the FEniCS project \[8\]. For this paper we have created a Python program, where the weak form of the boundary problem is coded as follows (only the important code snippets are presented):

```python
... # Define boundary conditions
bc = list()
for s in range(3,len(bcdefs)):
    bc.append( DirichletBC(W, ....)
... # Define variational problem
W = FunctionSpace(mesh, 'CG', 1)
u = TestFunction(W)
v = TrialFunction(W)
f = Constant(0)
m0 = 4. * pi * 1e-7
eps0 = 1. / 36. / pi / 1e-9
omega = 2. * pi * atof(f_o)
L2 = omega*omega*m0*eps0
Lambda2 = Constant( L2 )
a = (dot(grad(v), grad(t))
    - Lambda2 * v * t ) * dx
L = f*t*dx
V = Function(W)
solve( a == L, V, bc)
... # post-processing follows
```

In various experiments the field generated by the EFG-3B was simulated by a 2D and 3D finite element models. The frequency range for EFG-3B extends from 10KHz to 220MHz. The EM wave length at 220MHz is 1.36 m what enforces size of the finite element smaller than 13 centimeters. It is obvious that discretization of 7 x 5 x 3 m room with such a small elements (we have to remember that in the vicinity of antenna much finer discretization is necessary) will create huge amount of data making models computationally demanding.

The 2D model meshes (different densities up to 162465 nodes and 323447 triangles) were constructed with help of public domain codes: the 2D preprocessor polygen and mesh generator triangle \[9\]. A very dense mesh with size of triangles smaller than one centimeter allowed for very fine simulation even with linear field approximation over elements. The geometry of the 2D model is shown in Fig. 3—comparing it with Fig. 1, the reader will recognize the basic elements: the table (T), the antenna cross-section (A1 and A2) and the EUT location.

![Fig. 3. The geometry of the 2D model and E (magnitudes are in logarithmic scale) at $f_o = 10$ MHz](image)

The $E$ for operating frequency 10 MHz is also presented on Fig.3. Logarithmic scale was used to show the field direction, because the relative values of $|E|$ far from the antenna are of course very small at this frequency: $k_o^2 \approx 0.44$ and the wave effects may be neglected in (1). Fig. 4 shows relative magnitude of $E$ (20log(|$E$/max(|$E$|))) over the model. The logarithmic scale was narrowed to [-120dB...-40dB] range to score under the variation of $E$ at the EUT location.

![Fig. 4. 20log($\frac{|E|}{\text{max}(|E|)}$) at $f_o = 100$ MHz; gray-scale: -120dB (black) ÷ -40dB (white)](image)

Similar picture (notify the scale change) for $f_o = 100$ MHz is shown in Fig. 5—the wave effects are clearly visible at this frequency ($k_o^2 \approx 4.39$).

![Fig. 5. 20log($\frac{|E|}{\text{max}(|E|)}$) at $f_o = 100$ MHz; gray-scale: -120dB (black) ÷ -20dB (white)](image)
The geometry of 3D model is shown in Fig. 6. Only a half of the shielded room was simulated with the homogeneous Neumann boundary condition set on the symmetry plane.

The density of 3D mesh varied up to 78846 nodes and 422178 elements. The simulation time was approximately 10 times longer than for 2D model an thus we use the 2D simulator for optimal design and 3D model for validation only.

The results

The optimizer was based on the levmar library [4] implementing the Levenberg-Marquardt algorithm. We have optimized the length and angle of two reflectors mounted on the upper and lower part of the antenna. The optimal shape, increasing field intensity in the EUT zone by factor at least 3 (at 10 kHz) is shown in Fig. 7 (right inset) compared to the original antenna shape.

The modified antenna was better at the whole operating frequency range. It is shown in Fig. 8, showing the relative magnitude of the field intensity. The directed radiation pattern is clearly visible in Fig. 9, comparing electric field in the 2D model at $f_o$=100 MHz for the original antenna and for the modified one in two orientation: towards the table and towards the opposite wall.

Conclusion

The simplified models presented in this paper allowed us to increase the field strength by the factor 3 comparing to the original antenna shape.
